Interfacing the M68HC05 MCU to the MC145051 A/D Converter

By Mark Glenewinkel
CSIC Applications
Austin, Texas

Introduction

This application note describes the interface between Motorola's M68HC05 Family of microcontrollers and Motorola's MC145051 analog-to-digital converter (ADC). The MC145051 is a 10-bit, 11-channel, serial interface ADC. The microcontroller unit (MCU) interface must be able to "talk" to the MC145051 using a serial communication link. One of the most popular hardware modules available in the M68HC05 Family is the serial peripheral interface (SPI). This application note provides the hardware and software design to link the SPI module on the MC68HC705C8 MCU to the MC145051.

Not all M68HC05 Family members have SPI modules. An M68HC05 MCU without an SPI must interface to the MC145051 using a software driver. This method "bit bangs" a port of the MCU to communicate with the MC145051. Although not as efficient as the hardware SPI method, it provides MCUs without an SPI a means to retrieve data from the MC145051. This application note will utilize the MC68HC705K1 MCU to demonstrate the software driver routine.

MC145051 ADC

The MC145051 is a ratiometric 10-bit ADC providing 11 analog channels of conversion with an internal sample-and-hold. The MC145051 has an internal resistor capacitor (RC) clock oscillator to run its internal digital circuitry. The maximum conversion time for the MC145051 is 44 μ s with a maximum sample rate of 21.4 ksamples/s. If faster conversion time is needed, an MC145050 can be used that is the same as the MC145051 except it requires an external clock. With a 2.1-MHz clock, the MC145050 provides a 21 μ s conversion time and a maximum sample rate of 38 ksamples/s. The MC145051 operates with a single voltage supply between 4.5 and 5.5 volts. A serial interface is used to receive the channel address to convert and transmit converted values to the outside world.

Successive Approximation

The MC145051 utilizes successive approximation to convert the analog input signal to a digital value. This technique consists of comparing the unknown analog input to a known analog voltage created by a digital-to-analog converter (DAC). The digital number given to the DAC is the number that will eventually be the result of the ADC's output. This process of "guessing" the analog input voltage is similar to weighing with a balance. If you had three weights consisting of 1/2, 1/4, and 1/8 of a gram, you could measure something up to 1 gram within $\pm 1/16$ gram of the weight. One side of the scale would hold the unknown and the other side would contain various weights "guessing" at the weighted value of the unknown.

Consider how a 3-bit A/D converter would convert an unknown signal. **Figure 1** shows the block diagram of a very simple 3-bit A/D converter. A digital number is fed into the DAC and the DAC converts this to an analog voltage for the comparator to use. If the input analog voltage is larger than the DAC's output voltage, a 1 is the result of the comparison. If the input analog voltage is smaller than the DAC's output, a 0 is the result of the comparison. The result of the comparison is fed back into the successive approximation register. The control logic adds a smaller digitally "weighted" value to the DAC to "guess" at the input analog

voltage. This sequence continues until the smallest digital "weight" is used to guess at the input voltage. **Figure 2** illustrates this

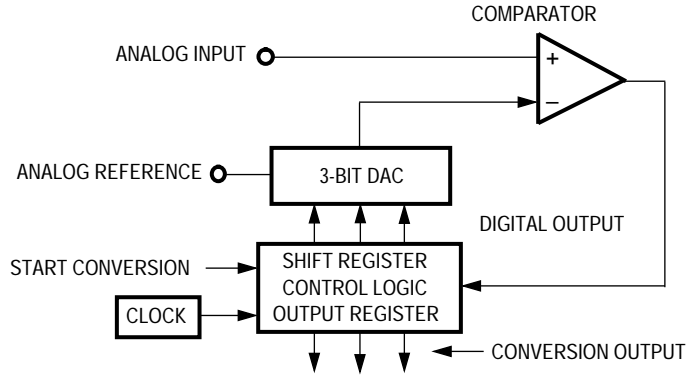

Figure 1. Simple 3-Bit A/D Converter

Figure 2. 3-Bit A/D Weighing Sequence

process with a graph that depicts the testing of a signal of magnitude between 3/8 and 4/8 of the full scale analog reference voltage. After the guesswork is done, the binary answer of 011 is written to an output register for further processing.

In this example, the input voltage does not change over the entire conversion process. We have assumed that the signal does not change and there is no noise to change the input voltage. In most cases a sample-and-hold circuit is used to sample a voltage signal and hold it for a specific length of time until the conversion process is complete.

The accuracy, linearity, and speed of the successive approximating A/D converter are dependent on the properties of the DAC and the comparator. The settling time of the DAC and the speed of the comparator determine the speed of the conversion process. Likewise, if the conversion demands more resolution, the time to convert will be lengthened. The DAC's non-linearity will result in non-linearities within the ADC. All of these factors affect the digital output result of the ADC.

Inside the MC145051

As stated earlier, the MC145051 will convert one of the 11 analog inputs into a 10-bit digital representation of the analog signal. The 10-bit digital value is transmitted to the outside world via a serial bus. **Figure 3** shows a block diagram of the MC145051. The sequence of starting a conversion, converting the voltage, and transmitting the result is:

1. The \overline{CS} signal is driven low to initialize the serial port that a 4-bit address is going to be received and the previous 10-bit digital result will be transmitted.
2. After the 4-bit mux address is received in the mux address register, one of the analog inputs is selected from the analog multiplexer. This signal is sent to the sample-and-hold to start the 10-bit conversion process.
3. While the 4-bit address is received, the 10-bit previously converted value is sent out on the D_{OUT} pin.
4. The internal clock drives the digital control circuitry, which in turn manipulates the successive approximation register until the 10-bit conversion is complete.

- Once the conversion is complete, the final value of the successive approximation register is written to the data register. The 10-bit result will stay here until it is queued to be sent out on the D_{OUT} pin on the next serial transmission. Also, the MC145051 will signal the ending of a conversion by driving the end-of-conversion (EOC) pin high. In some transmission scenarios, the \overline{CS} pin must be negated high before another transmission and conversion can occur.

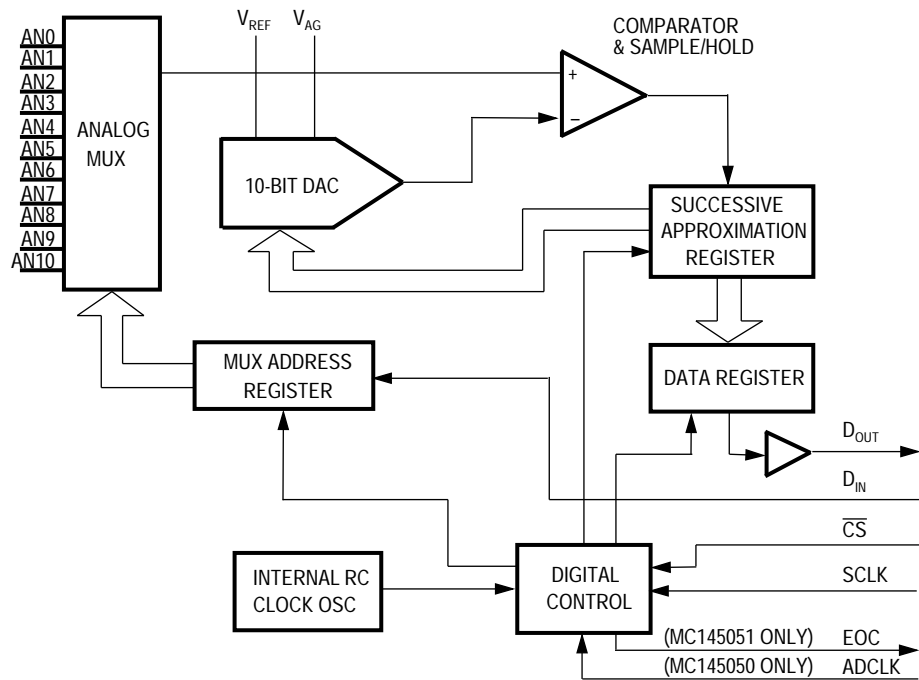

Figure 3. MC145051 Block Diagram

Application Note

Analog Interface

The analog input consists of the converter's high and low voltage reference pins and all 11 analog input pins. The analog specifications are listed in [Table 1](#).

Table 1. Analog Specifications

Symbol	Parameter	Min	Max
V_{REF}	DC Reference Voltage	$V_{AG} + 4.0$	$V_{DD} + 0.1$
V_{AG}	Analog Ground	$V_{SS} - 0.1$	$V_{REF} - 4.0$
V_{AI}	Analog Input Voltage	V_{AG}	V_{REF}

The MC145051 will take the voltage it samples off its analog input pin and convert it to a number equivalent to the ratio of the input voltage and the difference between the V_{REF} and V_{AG} . This number is the converter's digital representation of the sampled voltage input. [Figure 4](#) illustrates this ratio and describes an equation that predicts the ADC's conversion value. For example, if $V_{AI} = 2.34$ volts, then the 10-bit representation of that voltage is 479 or \$1DF.

Figure 4. A/D Conversion Ratio

Digital Interface

The digital interface to the MC145051 is composed of a serial data port that synchronously transceives data. Each digital pin's function is explained here.

\overline{CS} Active-Low Chip Select
 When asserted low, this pin initializes the chip to start performing A/D conversions. While high, the D_{OUT} pin is forced to a high-impedance state and the D_{IN} pin is disabled.

D_{OUT} Serial Data Out
 This pin serves as the serial output data of the A/D conversion result. After \overline{CS} is asserted low, D_{OUT} is driven with the most significant bit of the previous 10-bit A/D result. The value of D_{OUT} changes to the second most significant bit after the falling edge of the serial clock (SCLK). After 10 bits of transmission, D_{OUT} is driven low. The A/D result is always driven out of D_{OUT} most significant bit (MSB) first.

D_{IN} Serial Data In
 This pin serves as the input data line that receives the 4-bit address of the serial stream. The address is shifted on the rising edge of SCLK with the MSB being the first bit received. After all four bits have been received, the D_{IN} pin is ignored.

SCLK Serial Data Clock
 This pin is an input that drives the serial transmission lines. It drives the data shift registers so that the next mux address is received and the previous conversion is driven out.

EOC End-of-Conversion Output
 This pin is driven low on the 10th falling edge of SCLK. A low-to-high transition on EOC occurs after the A/D conversion is complete.

Application Note

The MC145051 is capable of various bit stream formats. The timing diagram used in this application note is shown in **Figure 5**. The MC145051 will wait patiently until its \overline{CS} pin is asserted low. This signifies that a serial clock will be driving the SCLK pin to transfer the next A/D channel address to be converted. At the same time, the MC145051 will be driving out the converted value of the previous conversion. After the 10-bit address is driven out of D_{OUT} , the \overline{CS} pin will be driven high to signify the end of the transmission process.

Figure 5. MC145051 Timing Diagram

Description of the MC68HC705C8 Interface

The following paragraphs describe the MC68HC705C8 interface.

Hardware

The MC68HC705C8 is one of the most popular members of the M68HC05 Family of 8-bit MCUs. It has the serial peripheral interface (SPI) that will be used to interface to the MC145051. The SPI is, in essence, an 8-bit serial shift register that can be manipulated by software instructions. The SPI can be programmed with different clock polarities and clock phases to correctly communicate with a number of devices. The SPI can also be configured to act as a master or a slave. Each signal of the SPI is explained below. For more detail on the SPI, consult *MC68HC705C8 Technical Data*, Rev. 1 (MC68HC705C8/D).

SCK Serial Data Clock

The SCK signal is used to synchronize the movement of data in and out of the SPI module. This pin is an output or an input dependent on whether the SPI is configured as a master or a slave. Data is shifted on one side of the clock edge and sampled on the other. The SCK signal can be configured to accommodate different serial peripheral bus structures.

MOSI Master Output, Slave Input

When the SPI is configured as a master, this pin is used as an output to shift the 8-bit serial data out with the most significant bit (MSB) first. The pin is used as a slave data input when the SPI is configured as a slave.

MISO Master Input, Slave Output

If the SPI is configured as a master, this pin is utilized as an input. When the SPI is in slave mode, the pin is used as an output.

$\overline{\text{SS}}$ Slave Select

When the SPI is a slave, this pin enables the SPI for an incoming transfer. As a master, this pin should be tied high.

To correctly interface to the MC145051, the SPI is configured as a master with the timing diagram shown in [Figure 6](#). This configuration

enables the SCK to drive out data with the MOSI pin on the rising edge and receive data with the MISO pin on the falling edge.

Figure 6. SPI Timing Diagram

The schematic used for this interface is shown in [Appendix A — MC68HC705C8/MC145051 Schematic](#). The MC68HC705C8 is clocked by a 4-MHz crystal circuit. This provides the MCU with a 2-MHz internal bus frequency and a 500-ns bus period or instruction cycle. The MC34064 is used as a low-voltage inhibitor circuit. This 3-pin, T0-92 device ensures that the reset pin is pulled low if the operating voltage to the MCU falls below 4.6 volts.

The SPI lines are connected to the appropriate pins on the MC145051. The MOSI pin drives data out of the MC68HC705C8 and into the D_{IN} pin of the MC145051. The D_{OUT} pin drives data out of the MC145051 pin into the MISO pin of the MC68HC705C8. Since the SPI is configured as a master, the SCK pin is driving the SCLK pin of the MC145051 and the \overline{SS} pin is tied high.

The MC68HC705C8 is programmed to utilize the SPI to read the MC145051. Channel AN0 of the MC145051 is used to read the voltage created by the 10 k Ω potentiometer between the V_{REF} and the V_{AG} levels. A 0.22 μ F capacitor is used between the V_{REF} and V_{AG} pins to filter out high frequency noise. This capacitor should be mounted as close to the MC145051 as possible. After the MC68HC705C8 receives the data from the MC145051, it is driven out onto ports B and C of the MC68HC705C8.

The circuit given in [Appendix A — MC68HC705C8/MC145051 Schematic](#) minimizes the noise often found in emulated systems. Instead of programming the MC68HC705C8, the M68HC05EVM can be used to emulate the MC68HC705C8. This evaluation module will not give as accurate an A/D reading as the circuit in [Appendix A —](#)

[MC68HC705C8/MC145051 Schematic](#), but allows more flexibility in code development than using a programmed MC68HC705C8.

Software

The flowchart for the SPI-driven MC145051 is shown in [Appendix B — MC68HC705C8/MC145051 Flowchart](#), and the actual M68HC05 assembly code is given in [Appendix C — MC68HC705C8/MC145051 Assembly Code](#). This code was written for a programmed MC68HC705C8. Extra lines of code were added so that the routine would perform in a standalone application.

For the SPI to "talk" to the MC145051, the SPI must be configured to match up with the MC145051 timing diagram, as shown earlier in [Figure 5](#). Also, two SPI transmissions must be sent to form a 16-bit transfer. Before any transmissions can start, the \overline{CS} pin must be asserted low. This initializes the MC145051 and tells it that a new mux address will be sent to it to start the conversion process. The first transfer sends the A/D channel number to the MC145051, and the MC145051 sends the upper eight bits of the previously converted value. These eight bits are written to the MSB of the 16-bit result register and to port B. The second transfer sends the A/D channel to the MC145051 but the MC145051 ignores it because it is not needed. The MC145051 sends the 705C8 the two least significant bits (LSB) from the previously converted value. These two bits are the two most significant bits in the received SPI data. This byte is written to the LSB of the 16-bit result register and to port C. After both transmissions are done, \overline{CS} is negated high. Port B and port C now have the 10-bit A/D value of the previous conversion. This output value on port B and port C is illustrated in [Figure 7](#). The routine will now sit in an infinite loop waiting for a reset.

Figure 7. A/D Value on Port B and Port C

The following example is provided to test the software routine. Follow these steps after programming the MC68HC705C8 with the code in [Appendix C — MC68HC705C8/MC145051 Assembly Code](#) and constructing the schematic in [Appendix A — MC68HC705C8/MC145051 Schematic](#).

1. Set the potentiometer to a reading of 2.20 volts.
2. If $V_{REF} - V_{AG}$ is exactly 5.00 volts, the A/D should convert to a reading of 450 or \$1C2. (See [Figure 4](#).)
3. Power on the circuit.
4. The A/D value will be outputted on port B and port C. This value is the previously converted value. Since there was no previous conversion, the data will be garbage.
5. Pull the \overline{RESET} pin low and then high. The routine will run again, and the previous value of the AN0 channel conversion is represented on port B and port C. The value for port B should be \$70 and port C should be \$80. The result might differ by a least significant bit (LSB). (See [Figure 7](#).)

This routine is the simplest example to test and learn the interface from the MC68HC705C8 to the MC145051. Notice that the mux address must be in the high nibble of the byte before it is written to the SPI data register. Also, since this routine was hard-coded, the A/D channel was already known and written into memory. The code can be easily adapted as a subroutine, which requires that the channel to be converted is an input to the subroutine. If the application requires that successive A/D conversions are made, make sure that the MC145051 has enough time to convert the present channel before initializing another conversion. If needed, the MC145051 provides the EOC pin. During a conversion process, the pin is held low. After conversion is complete, the pin is driven high. Another port pin on the MC68HC705C8 might be used to read the EOC pin.

Description of the MC68HC705K1 Interface

The following paragraphs describe the MC68HC705K1 interface.

Hardware

With only 16 pins, the MC68HC705K1 is one of the smallest members of the M68HC05 Family. It has a total of 504 bytes of erasable programmable read-only memory (EPROM) and includes 10 input/output (I/O) pins. The schematic for the MC68HC705K1 to MC145051 interface is shown in [Appendix D — MC68HC705K1/MC145051 Schematic](#). With this interface, the M68HC705KICS development board was used to write and test the code. The circuitry surrounding the MC145051 is the same as in the MC68HC705C8 design. The only changes are the serial pins of the MC145051. These pins are connected to the emulation header of the M68HC705KICS board. This emulation header has the exact pinout of the MC68HC705K1. The pins used to drive the MC145051 on the MC68HC705K1 are:

- Port A, Bit 0 This I/O pin (\overline{CS}) is configured as an output to drive the \overline{CS} pin on the MC145051.
- Port A, Bit 1 This I/O pin (SER_CLK) is configured as an output to drive the serial clock of the serial transmission bus.
- Port A, Bit 2 This I/O pin (SER_OUT) is configured as an output to drive the serial data out and into the D_{IN} pin of the 5051.
- Port A, Bit 3 This I/O pin (SER_IN) is configured as an input to receive data driven from pin D_{OUT} of the MC145051.

The emulation test circuit may also be configured as a standalone design. For further information on programming the MC68HC705K1, consult the *MC68HC705K1 Technical Data*, Rev. 1 (MC68HC705K1/D) and the M68HC705KICS development board documentation.

Software

The flowchart for the bit-banged-driven MC145051 is shown in [Appendix E — MC68HC705K1/MC145051 Flowchart](#), and the actual M68HC05 assembly code is given in [Appendix F — MC68HC705K1/MC145051 Assembly Code](#). Bit-banging is the process of toggling I/O pins with software instructions to emulate a certain piece of hardware peripheral. This bit-banged routine was written especially for the MC145051. It is not a full featured representation of the MC68HC705C8 SPI module. Enhancements to the routine were not included to maximize the efficiency of the code.

As stated in the preceding [Hardware](#) section, I/O pins have been used to send out the correct serial transmission protocol to the MC145051. The M68HC05 CPU provides special instructions to specifically manipulate single I/O pins. The MC145051 serial stream shown in [Figure 5](#) will be re-created by four I/O pins on the MC68HC705K1.

The best way to describe the code is to list each segment of the code and explain its purpose to bit-bang the MC145051. PA2 is shorthand for port A, bit 2.

Equivalents

PA0 = $\overline{\text{CS}}$

PA1 = SER_CLK

PA2 = SER_OUT

PA3 = SER_IN

Initialize Port A

$\overline{\text{CS}} = 1 \Rightarrow$ output

SER_CLK = 0 \Rightarrow output

SER_OUT = 0 \Rightarrow output

SER_IN = 0 \Rightarrow input

Begin A/D Acquisition

The $\overline{\text{CS}}$ pin is driven low to start the serial transmission.

The CHANNEL RAM byte is read. The address is in the low nibble of the byte. The 16-bit RESULT registers are cleared and a copy of CHANNEL is stored in TMP_CHN for future use. When emulating, make sure that location \$E2 is initialized with the A/D channel \$00.

Initialize Loop1

Set the index register to 4.

Read the serial input pin — Start of Loop 1

The branch-if-clear instruction is used to read SER_IN. The purpose of this is to transfer the logic state on the SER_IN pin to the carry bit (C). No branch is taken. The next line of code is always executed. Two rotate left instructions rotate the C bit into the 16-bit RESULT register composed of RESULT and RESULT+1. The first bit read on SER_IN is the MSB of the previous A/D result from the MC145051.

Write the serial output pin

The TMP_CHN is rotated left. Bit 4 of TMP_CHN is read. If it is high, a 1 is written to SER_OUT. If it is low, a 0 is written to SER_OUT. This first transmitted bit is the MSB of the 4-bit A/D channel address.

Clock the serial clock pin

The SER_CLK pin is written high and then written low.

Is Loop 1 done?

The index register is decremented and checked to see if it is 0. If IX is not 0, the code is executed at the start of Loop 1. This loop continues until four transmissions are completed.

Initialize Loop 2

Set the index register to 6.

Read the serial input pin — Start of Loop 2

This is the same code that was executed at the start of loop 1 above. Notice that loop 2 does not transmit any more bits on SER_OUT. This is because the MC145051 ignores the last six transmitted bits because it has already received the four address bits it needs.

Clock the serial clock pin

The SER_CLK pin is written high and then written low.

Is Loop 2 done?

The index register is decremented and checked to see if it is 0. If IX is not 0, the code is executed at the start of Loop 2. This loop continues until six transmissions are completed.

Negate CS

A 1 is written to the \overline{CS} . This completes the serial transmission to the MC145051.

Since this code was written for emulation on the M68HC705KICS board, it is easy to experiment with different applications. The code can be easily adapted to fit any custom application that needs 10-bit A/D data.

Layout Considerations

There are many things to consider when laying out mixed signal designs such as the MC145051 and the M68HC05 MCU. The accuracy of the MC145051 may be greatly affected if proper layout design is not followed. Listed here are some things to check to ensure the accuracy of your A/D converter. For more in-depth study of ADC layout issues, consult *Reducing A/D Errors in Microcontroller Applications* (AN1058/D).

- Physically separate critical analog circuits from the digital circuits of the MCU. If possible, split your board in half to separate analog and digital circuits. Each half will have its own power and ground system.
- Do not let analog input line traces cross digital traces. If this has to happen, make sure they cross at right angles to each other.
- Use power or ground traces to isolate the analog-input pins from the digital pins.
- Bypass the power supplies to the proper ground at the MC145051 power pins with quality ceramic capacitors. Keep the bypass capacitors lead lengths as short as possible.

- To bypass low frequency power supply noise, use tantalum or aluminum electrolytic capacitors of 5 to 20 μF . These should be placed near the point where the power supplies enter the board.

Application Note

Appendix F — MC68HC705K1/MC145051 Assembly Code

*
* Program Name: K1_5051.ASM (705K1 to 145051 interface)
* Revision: 1.00
* Date: September 22, 1993
*
* Written By: Mark Glenewinkel
* CSIC Applications
*
* Assembled Under: P&E Microcomputer Systems IASM05

* *****
* * Revision History *
* *****

* Rev 1.00 09/22/93 M.R. Glenewinkel
* Initial Release

* Program Description:

* This software routine provides a way for MCUs with no
* SPI module on chip to interface to the Freescale MC145051
* 10 bit, 11 channel analog to digital converter.

* This program specifically uses the MC68HC705K1 MCU to
* test the code. The HC705K1 "bit bangs" the 5051 with the
* appropriate serial data transfer the 5051 understands.

* For more information, please consult Freescale Application
* Note AN1228/D.

*
